

Autonomous Control of Aircraft for Communications and Electronic Warfare: The Promises of Recent Artificial Intelligence Literature

Sean Carver, Ph.D. at Data Machines Corporation

May 14, 2021

Abstract

We pose an unsolved problem in autonomous control of aircraft for communications and jamming (electronic warfare). We aim to provide helpful pointers to literature offering approximately optimal solutions to related problems—such as cyber-security, precision farming, and search and rescue. Solutions to these related problems promise applicability to diverse scenarios beyond the scope of the original works—including to the important scenario considered here.

The problem we address lies within the fields of adversarial Multi-Agent Reinforcement Learning (MARL) and active sensing. In our problem, two opposing factions (labeled “blue” and “red”) compete to win a zero-sum/purely adversarial game. The blue side tries to maintain communication links between ground-based assets with a fleet of “comms;” whereas the red side tries to jam this network with a fleet of “jammers.” An Unmanned Aerial Vehicle (UAV) becomes a comm or a jammer when fitted for one of these purposes.

Each faction lacks access to the state of the opposing side, and must infer this state probabilistically through positioning its fleet for best sensory performance and localization (active sensing). Moreover, the ground troops of each side, when also positioned appropriately, have the possibility of shooting down any of their adversary’s UAVs. Finally, the blue side must simultaneously achieve its objective of keeping units on the ground in communication. Despite best efforts, different units/UAVs can fall in and out of communication with their respective headquarters, making each of the blue and red factions a multi-agent collection, fully cooperating among itself, but with different information, to fight its adversary having opposing goals.

Our contribution poses this problem while pointing to literature for possible ideas for moving the field forward. Finally, we pose a hierarchy of simpler-than-reality mini-games for efficiently investigating solutions leading to a successful implementation for the full adversarial problem in real-world combat.

1 Introduction

If unfortunate circumstances compel our leaders to order our armed forces to take a city from an adversary, the command headquarters on the ground would benefit from constant two-way communication with all its other units during the conflict.

In the fog that accompanies such struggles, our forces cannot rely on our enemy’s network of cell towers to keep in touch. Instead, two way radios, linked by a network of “comms” (UAVs for communication) will hopefully allow our friendlies to stay connected.

While vastly better than cell phones, such a network has its own set of challenges. Indeed, our adversaries clearly prefer to keep us out of communication. To pursue this preference, they may send up jammers (UAVs for blocking communication). Thus begins a delicate dance of each side positioning its fleet to best find the other’s birds and in so doing best keep or block communications.

We study the question of how each side can control its fleet by autonomously ordering and carrying out flight and communications- electronics operation instructions (CEOI) to optimally achieve its objectives. We are interested in the strategies for both sides, because to defeat our enemy, we must understand the intelligent countermeasures they may take. Moreover, in a real war, our side may choose to fly both comms and jammers, requiring strategies for both roles.

Much recent literature has tackled the problem of optimal search and rescue, and several similar scenarios. This effort clearly relates to the problem at hand because, as with rescue, each of our sides benefits from successfully inferring the positions of targets. But there is a difference between search and rescue and electronic warfare. People being rescued presumably want to be found and will presumably cooperate with this effort. But in electronic warfare participants always aim to keep their locations from the other side. As a result, while search and rescue can succeed with a purely active sensing and optimal control solution, in our scenario, we need to learn to counter an opponent’s strategy. To this end, we propose to apply artificial intelligence: specifically, adversarial multi-agent reinforcement learning.

This paper reviews the literature relevant to our problem in electronic warfare, but will close with a very brief discussion presenting ideas for applying this work to other domains of interest to us, notably cybersecurity.

2 Scenario

The field of interest is a square in the Euclidean plane. In this field, there is a “source,” or “sender,” labeled S , a receiver, labeled R , and n different “jammers,” labeled J_1, \dots, J_n . We do not assume that the ability to communicate is symmetric—a separate calculation is needed when the roles of sender and receiver are reversed. Additionally there are m different comms to facilitate communication.

3 Optimal Placement Of Comms

Let c_i denote positions of comms and let j_k denote positions position of jammers. If these quantities are known, we can compute the probability of a successful communication between the headquarters and an asset (see more details below). We denote this probability

$$P(\text{transmission}|c_i, j_k)$$

Some choices still need to be made about how this probability will be computed, but it shouldn't be hard. By total probability,

$$P(\text{transmission}|c_i) = \sum_k P(\text{transmission}|c_i, j_k)P(j_k)$$

It is a sum rather than an integral because we only consider grid points as possible locations. That may need to be generalized. The second factor of each term in the sum is the posterior probability already coded for computation and described below.

A final step in the computation is a optimization over the comm positions c_i .

4 TL;DR

Let $P_j(d_j)$ be the power of jammer j at the receiver, at distance d_j . Let $P_S(d_S)$ be power of the source at the receiver, at distance d_S . Let P_N be the power of the ambient noise.

These functions are given by $P_j = \frac{M_j}{d_j^2}$, for $j = 1, \dots, n$ and $P_S = \frac{M_S}{d_S^2}$; P_N is a constant.

The probability of a successful transmission is given by

$$\text{sigmoid} \left(10 \log_{10} \left(\frac{P_S(d_S)}{P_1(d_1) + P_2(d_2) + \dots + P_n(d_n) + P_N} \right) \right)$$

The quantity in the sigmoid is the strength expressed in decibels, of the signal against the background that includes all jammers and the ambient noise, see Equation (1) in reference [1]

5 Some thoughts about the man-in-the-middle

Billy had alerted us to the fact that it was more than just distance to jammer-jammers in the line of sight were more potent than those off of it.

I spent a long time trying to justify putting this feature explicitly in the model. But the model above seemed most consistent with what I was reading in the literature and it made sense. It is distance to receiver that matters. A man in the middle generally will jam the receiver, unless distances are great enough, the ambient noise is small enough, and the

proportionality constant of the jammer is small enough compared to the proportionality constant of the sender. This makes sense to me.

There is such a thing as electromagnetic interference. According to Wikipedia: “The effect of unwanted energy due to one or a combination of emissions, radiations, or inductions upon reception in a radiocommunication system, manifested by any performance degradation, misinterpretation, or loss of information which could be extracted in the absence of such unwanted energy.” My reading of this is this: interference happens upon the reception of the signal, in the circuits of a radiocommunication system, not with signal itself. Electromagnetic waves don’t interact, as far as I am aware, but it can be impossible to pick out the signal in the noise.

Having said all that, a directional receiving antenna would sharpen the effect of a man-in-the-middle jammer, versus one off to the side, but for the moment I’m keeping it simple and assuming the antennae have no preferred direction. Could change that next, though, by assuming they are optimally directed to receive the signal in a particular orientation, and to reject signals in substantially different directions.

6 Power

The power of the radio signal from a point source at a distance r is given by (assuming the free-space propagation loss model):

$$P_{\text{signal}}(d) = \frac{M}{d^2},$$

where M is a proportionality constant that depends on units, and even with the same units, can be different for different senders. Note that M is the power of the signal at distance 1. The value of M may be known for friendlies but need to be estimated for jammers. Equation (1) in reference [2], showed a similar equation for “path loss” relaxing the free-space propagation loss model with a proportionality exponent possibly different from 2. It seems that the units of distance are important in this model—see reference [2]. I note this observation for the future as I intend to use the free-space propagation loss model for now.

Equation (5) in reference [3] gives

$$M = \frac{P_T G_T G_R}{4\pi},$$

where P_T is the power of the transmitter, G_T is the gain of the transmitter in the direction of the receiver, and G_R is the gain of the receiver in the direction of the transmitter. Presumably the transmitter could be either the jammer or the source. Reference [2], gives a similar equation that may not be entirely consistent that has a dependence on wavelength, Equation (1). The basic thing I get from this is kind of obvious for anyone raised in the era before cable television—it depends on the orientation of the antenna how strong the signal. Again, I am just putting this observation in this document for the future. For the first cut the power received by the antenna is just a function of the distance to the transmitter, not the orientation of the antenna.

7 Jamming

One reference I have [3] talks about channel capacity as the maximum bit rate $S \rightarrow R$, under the assumption of error correcting codes, etc. So it seems in this paradigm that it is not whether you are jammed or not, but how many bits get through per second. In several references, including this one there is a noise term which adds power to the jammer in a symmetric way. When the decibels in the equation above drops below the 0, the channel capacity falls below the bandwidth of the channel.

I am going to ignore the details of channel capacity and error correcting codes and just say probability of transmission is a function of the ratio of the powers of signal to background, expressed as a sigmoid of decibels.
